Abstract

The preBötzinger Complex (preBötC) generates the mammalian respiratory rhythm, but its core circuit architecture remains debated. While theories propose a “mutually inhibitory ring” logic, verifying this topology requires disentangling concurrent synaptic interactions in genetically defined neurons. We applied a novel conductance inference method to whole-cell recordings from VgluT2-expressing (excitatory) and VGAT-expressing (inhibitory) neurons in the rhythmic brainstem slice. We found that the core rhythmogenic kernel consists of a self-exciting inspiratory VgluT2 population coupled to a reciprocal inhibitory half-center formed by inspiratory and expiratory VGAT populations. Unlike in intact preparations, the expiratory VgluT2 population was passive, confirming its role as a conditional oscillator recruited only by metabolic demand. These results provide direct functional verification of the minimal synaptic architecture required to coordinate respiratory population activity.

1 Introduction

The preBötzinger Complex (preBötC) is the primary site of respiratory rhythm generation in mammals (Smith et al., 1991). While the intrinsic properties of preBötC neurons have been extensively characterized, understanding the network architecture—specifically how excitatory and inhibitory synaptic populations interact to generate robust rhythmicity—remains a fundamental challenge. A major hurdle has been the difficulty in disentangling concurrent excitatory and inhibitory synaptic drives during the respiratory cycle, particularly in genetically defined cell types (Koizumi et al., 2013). Crucially, this study focuses on the functional connectome and dynamic synaptic drives that coordinate population activity, rather than the intrinsic or network-level mechanisms (such as pacemaker currents) that generate the rhythm itself.

In a recent study, we developed a novel computational inference technique (Molkov et al., 2025) to decompose total synaptic conductance into its excitatory and inhibitory components using single-trace current-clamp recordings. By applying this method to the *in situ* arterially perfused preparation, we successfully mapped the dynamic “synaptic fingerprints” of respiratory neurons, revealing the functional connectivity between excitatory (VgluT2⁺) and inhibitory (VGAT⁺) populations that underpins the intact respiratory network.

However, the *in situ* preparation preserves a high degree of network complexity and external inputs. The acute brainstem slice preparation remains the gold standard for investigating the minimal, intrinsic circuitry necessary for rhythm generation. It is widely hypothesized that the slice contains a “reduced” circuit—a core kernel of the network capable of sustaining rhythmicity in the absence of wider pontine and feedback loops (Smith et al., 2007). Yet, identifying the precise topology of this reduced circuit and how it differs from the intact network requires rigorous quantitative analysis of synaptic interactions.

In this study, we apply our conductance inference methodology to the rhythmic slice preparation to define the core circuit architecture of the preBötC. We combined whole-cell recordings from genetically identified VgluT2-expressing glutamatergic and VGAT-expressing inhibitory neurons with computational analysis to reconstruct their dynamic synaptic inputs.

Our analysis reveals a distinct, reduced circuit topology in the slice. We identify four functional populations based on neurotransmitter identity and firing phase. Crucially, we demonstrate that while inspiratory rhythm is driven by recurrent excitation within the VgluT2 population, the phasic transitions

are enforced by specific reciprocal inhibitory interactions between VGAT populations. Furthermore, we find that unlike in the intact preparation, the VgluT2-expressing expiratory population in the slice is largely passive, receiving inhibition but providing no significant synaptic drive. These findings allow us to propose a “minimal” circuit model—consisting of a self-exciting inspiratory source coupled with a half-center inhibitory oscillator—that constitutes the essential machinery for respiratory rhythm generation *in vitro*.

2 Methods

2.1 Experimental Procedures

All animal procedures were approved by the Animal Care and Use Committee of the National Institute of Neurological Disorders and Stroke (Animal Study Proposal number: 1154–21). We used the VgluT2-tdTomato mouse line (derived from Slc17a6-cre crossed with Rosa-CAG-LSL-tdTomato) to identify VgluT2-expressing glutamatergic neurons. In some experiments, VgluT2-tdTomato-ChR2-EFYP mice were used.

Rhythmically active medullary slice preparations (300–400 μm thick) were obtained from neonatal (P3–P8) mice of either sex. Slices were superfused (4 ml/min) with artificial cerebrospinal fluid (ACSF) containing (in mM): 124 NaCl, 25 NaHCO₃, 3 KCl, 1.5 CaCl₂, 1.0 MgSO₄, 0.5 NaH₂PO₄, and 30 D-glucose, equilibrated with 95% O₂ and 5% CO₂ (pH 7.35–7.40 at 27°C). Rhythmic respiratory activity was maintained by elevating the K⁺ concentration to 8–9 mM.

Inspiratory motor output was recorded from hypoglossal (XII) nerve rootlets using fire-polished glass suction electrodes (50–100 μm inner diameter). PreBötC inspiratory population activity was monitored using macro-patch recordings (150–300 μm pipette tip). Signals were amplified (50,000–100,000 $\times$; CyberAmp 380), band-pass filtered (0.3–2 kHz), and digitized at 10 kHz (PowerLab or CED).

Whole-cell voltage- and current-clamp recordings were performed using a HEKA EPC-9 amplifier and PatchMaster software. Recording electrodes (borosilicate glass, 4–6 M Ω) contained (in mM): 130 K-gluconate, 5 Na-gluconate, 3 NaCl, 10 HEPES, 4 Mg-ATP, 0.3 Na-GTP, and 4 sodium phosphocreatine (pH 7.3 with KOH). Measured potentials were corrected for a liquid junction potential of –10 mV. Series resistance was compensated on-line by $\sim 80\%$.

2.2 Data Preprocessing

Raw experimental data consisting of time series recordings of injected current ($I_{inj}(t)$), membrane potential ($V_m(t)$) and integrated hypoglossal nerve activity ($p(t) = \int \text{XII}(t)$) were processed to extract cycle-dependent characteristics. To reduce high-frequency noise while preserving edge information, a median filter was applied to all channels.

2.3 Cycle Detection and Phase definition

Cycles were defined based on the periodic activity observed in the control signal $p(t)$. The signal was first preprocessed and smoothed using a median filter. A robust threshold detection algorithm was employed to identify cycle onsets.

The detection threshold θ was determined automatically to ensure robustness against outliers and varying background noise. We calculated the median $M = \text{median}(p)$ and the 99th percentile P_{99} of the signal distribution. The detection threshold was defined as the midpoint of the robust dynamic range:

$$\theta = M + 0.5 \cdot (P_{99} - M) \quad (1)$$

This approach effectively identifies the active phase of the cycle while ignoring high-amplitude artifacts or baseline fluctuations.

A cycle start event was defined as a rising edge crossing θ (i.e., $p[i-1] < \theta \leq p[i]$), with the additional constraint that the signal must remain above the threshold for a minimum duration (default 10 samples) to reject transient spikes.

The phase $\phi(t)$ was calculated linearly between consecutive cycle start times T_n and T_{n+1} :

$$\phi(t) = \frac{t - T_n}{T_{n+1} - T_n}, \quad T_n \leq t < T_{n+1} \quad (2)$$

where t is the time, and $T_{n+1} - T_n$ represents the period of the n -th cycle.

2.4 Synaptic Conductance Reconstruction

To decompose the synaptic inputs into excitatory and inhibitory components, we utilized a "wedge diagram" method analogous to the technique described in previous studies (Molkov et al., 2025). This approach relies on the current balance equation:

$$I_{inj}(t) = g_L(V_m(t) - E_L) + g_e(t)(V_m(t) - E_e) + g_i(t)(V_m(t) - E_i) + C \frac{dV_m}{dt} \quad (3)$$

where $g_L, g_e(t), g_i(t)$ are leak, excitatory, and inhibitory conductances, and E_L, E_e, E_i are their respective reversal potentials. Assuming the membrane time constant $\tau = C/g_L$ is fast relative to synaptic fluctuations ($dV_m/dt \approx 0$) and that the synaptic conductances depend on the phase of the cycle $\phi(t)$ rather than explicitly on time (i.e., $g_e(t) \approx g_e(\phi(t))$ and $g_i(t) \approx g_i(\phi(t))$), the relationship between injected current I_{inj} and membrane potential V_m is linear at any given phase ϕ :

$$I_{inj}(t) \approx G_{tot}(\phi)V_m(t) + I_0(\phi) \quad (4)$$

where $G_{tot}(\phi) = g_L + g_e(\phi) + g_i(\phi)$ is the total conductance and $I_0(\phi)$ represents the regression intercept (current y-intercept).

To estimate these parameters, we discretized the cycle phase $\phi \in [0, 1]$ into 1000 bins. For each phase bin, we collected all data points $(V_m(t_k), I_{inj}(t_k))$ where the phase $\phi(t_k)$ fell within that bin. A simple linear regression of I_{inj} versus V_m was performed on these points to determine the slope $G_{tot}(\phi)$ and the intercept $I_0(\phi)$ (Figure 1A).

The leak parameters (g_L and E_L) were estimated by evaluating the total current at the reversal potentials of the synaptic currents. We calculated the theoretical currents at the inhibitory and excitatory reversal potentials for each phase:

$$Q_i(\phi) = G_{tot}(\phi)E_i + I_0(\phi) \quad (5)$$

$$Q_e(\phi) = G_{tot}(\phi)E_e + I_0(\phi) \quad (6)$$

Since the driving force for inhibition is zero at E_i , $Q_i(\phi)$ represents the sum of leak and excitatory currents. Assuming there exists a phase where excitation is minimal (zero), the maximum value of $Q_i(\phi)$ corresponds to the pure leak current at E_i , denoted I_{Li} . Similarly, the minimum value of $Q_e(\phi)$ corresponds to the leak current at E_e , denoted I_{Le} (assuming zero inhibition):

$$I_{Li} = \max_{\phi} Q_i(\phi) = g_L(E_i - E_L), \quad I_{Le} = \min_{\phi} Q_e(\phi) = g_L(E_e - E_L) \quad (7)$$

The leak conductance g_L and reversal potential E_L are derived from these values:

$$g_L = \frac{I_{Le} - I_{Li}}{E_e - E_i}, \quad E_L = E_i - \frac{I_{Li}}{g_L} \quad (8)$$

Finally, the excitatory and inhibitory conductances for each phase were calculated explicitly as:

$$g_e(\phi) = \frac{Q_i(\phi) - I_{Li}}{E_i - E_e} \quad (9)$$

$$g_i(\phi) = \frac{Q_e(\phi) - I_{Le}}{E_e - E_i} \quad (10)$$

This method allows for the robust reconstruction of dynamic synaptic conductances from single-trace current-clamp recordings with varying injected current steps or from voltage-clamp recordings with varying voltage steps (Molkov et al., 2025). The geometric relationship between total conductance (G_{tot}) and the current y-intercept (I_0) is visualized in the "wedge plot" (Figure 1B), where the trajectory is bounded by the limits of pure excitation and inhibition. The final reconstructed conductances $G_{exc}(\phi)$ and $G_{inh}(\phi)$ are shown in Figure 1C.

3 Results

3.1 Synaptic Inputs Define Firing Phenotypes

We analyzed the synaptic inputs received by respiratory neurons to understand how these inputs shape their firing phenotypes. Figure 2 illustrates the inferred excitatory and inhibitory conductances for

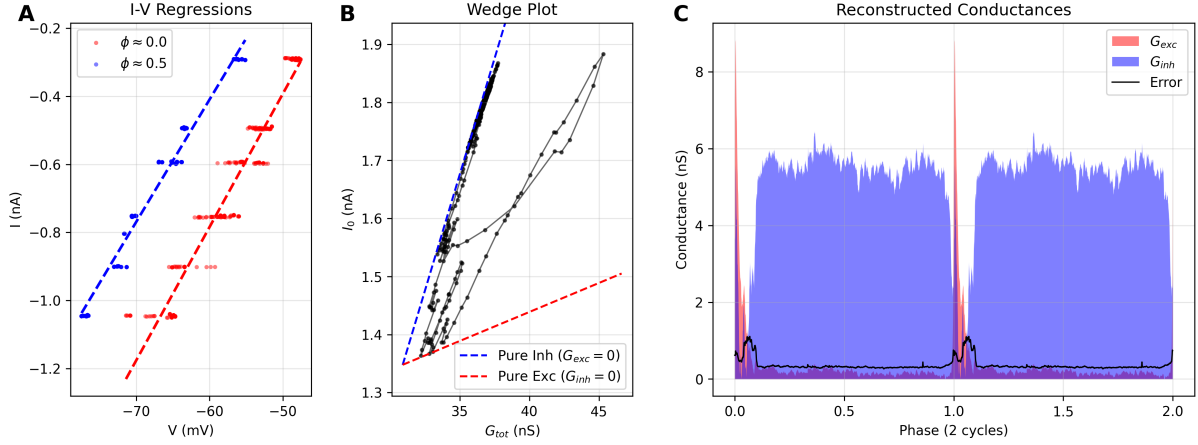

Figure 1: Illustration of the synaptic conductance reconstruction methodology. **(A)** Representative linear regressions of injected current (I) versus membrane potential (V) for two different phases of the respiratory cycle ($\phi \approx 0$, red; $\phi \approx 0.5$, blue). The slope corresponds to the total conductance G_{tot} , and the intercept represents the current y-intercept I_0 . **(B)** "Wedge plot" showing the trajectory of the system in the G_{tot} vs. I_0 plane across the respiratory cycle (black loop). Theoretical boundaries for pure excitation ($G_{inh} = 0$, red dashed line) and pure inhibition ($G_{exc} = 0$, blue dashed line) are determined by the leak parameters. The position of the trajectory relative to these boundaries dictates the decomposition into excitatory and inhibitory components. **(C)** Reconstructed time course of excitatory (G_{exc} , red) and inhibitory (G_{inh} , blue) conductances over two respiratory cycles. The black line indicates the standard error of the estimation.

representative inspiratory and expiratory neurons, covering both excitatory (VgluT2⁺) and inhibitory (VGAT⁺) populations.

Inspiratory neurons (Figures 2a and 2c) consistently exhibited a specific pattern of synaptic input: they received phasic inspiratory excitation during the burst phase, concurrent with tonic expiratory inhibition during the inter-burst interval. This combination of drive and disinhibition supports their active phase during inspiration.

Conversely, expiratory neurons (Figures 2b and 2d) displayed a distinct connectivity profile. They received strong phasic inhibition during the inspiratory phase, which effectively shunted their activity during the cycle's active phase. Notably, we encountered only a single VgluT2-expressing neuron with this expiratory firing phenotype. This rare VgluT2-E neuron, like the more numerous VGAT-E neurons, received no significant excitatory or inhibitory input during the expiratory phase, suggesting its firing is potentially intrinsic or driven by tonic baseline properties rather than specific phasic synaptic drive.

Critically, these synaptic input patterns appear to define the firing phenotype (inspiratory vs. expiratory) independent of the neuron's own neurotransmitter identity. Both VgluT2⁺ (excitatory) and VGAT⁺ (inhibitory) neurons within the same firing class shared identical synaptic input profiles.

3.2 Population Summary of Conductances

To quantify the synaptic drive across the network, we aggregated the estimated excitatory and inhibitory conductances for all four genetically defined populations: VGAT-I, VgluT2-I, VGAT-E, and VgluT2-E (Figure 3). The population-level results substantiate that the synaptic coordination is robust across all categories. Specifically, inspiratory-active populations (VGAT-I and VgluT2-I) receive strong phasic excitation concurrent with inspiration, while expiratory-active populations (VGAT-E and VgluT2-E) are dominated by profound phasic inhibition during the same period.

Quantitative results for the reconstructed conductances (mean $\pm$ SEM) are summarized in Table 1. Notably, the VgluT2-E population, while sparse in our sample, exhibits a "latent" connectivity profile receiving strong inspiratory inhibition but providing no significant excitatory drive during expiration in the slice preparation.

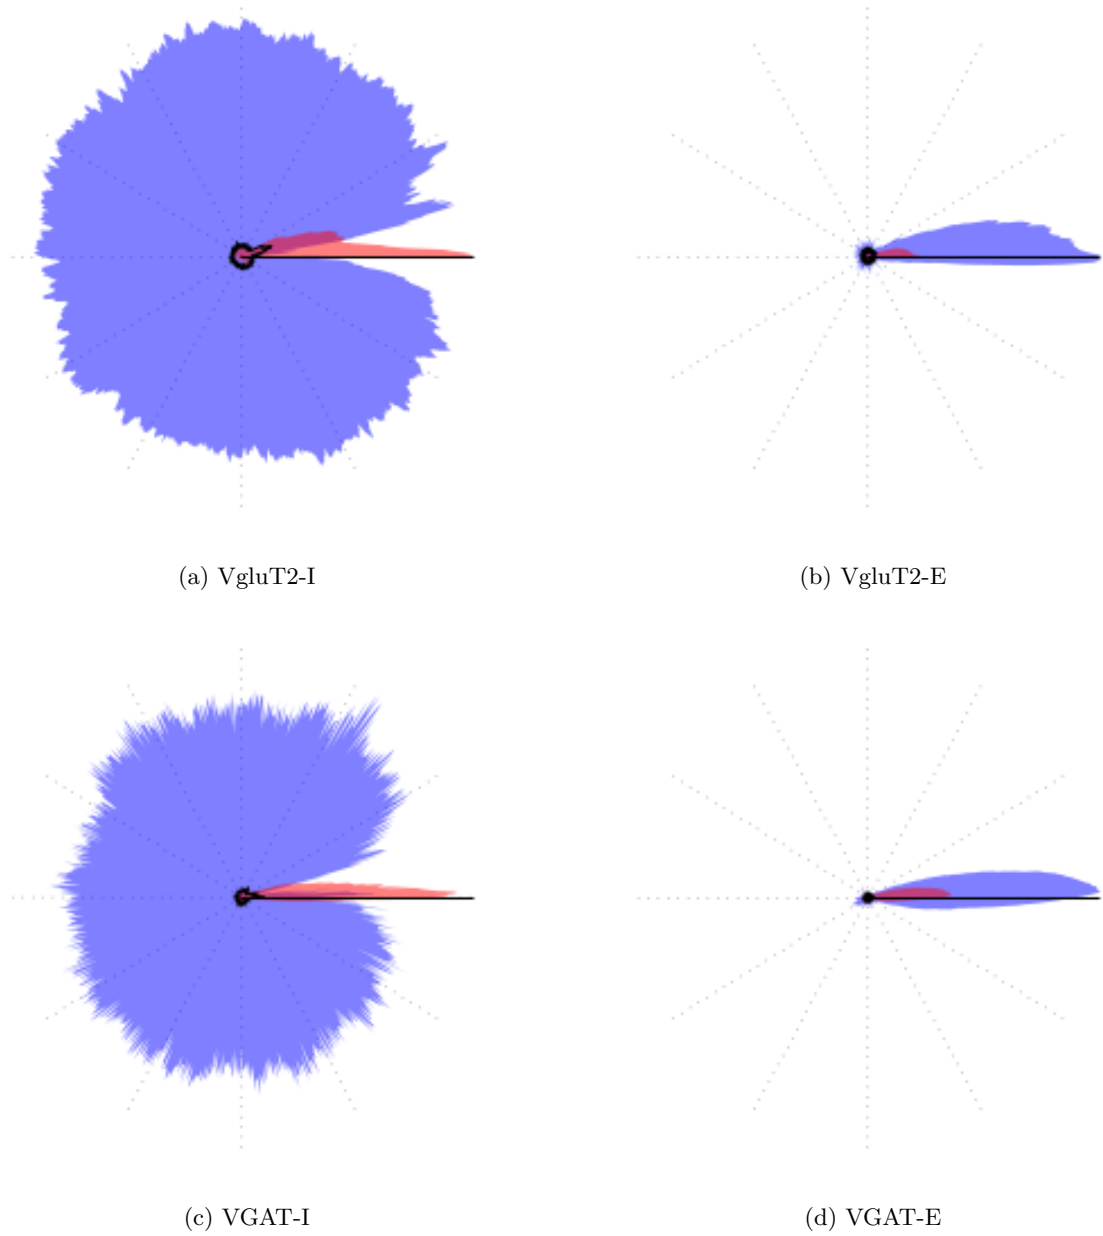

Figure 2: Representative cells for each neurotransmitter and firing phenotype. Panels exhibit inferred synaptic conductances for different cell types: (a) VgluT2 Inspiratory, (b) VgluT2 Expiratory, (c) VGAT Inspiratory, and (d) VGAT Expiratory. VgluT2 (vesicular glutamate transporter 2) indicates excitatory (glutamatergic) neurons, while VGAT (vesicular GABA transporter) indicates inhibitory (GABAergic/glycinergic) neurons.

Table 1: Summary of reconstructed synaptic conductances across neuronal populations.

Group (N)	Phase	G_{exc} (nS)	G_{inh} (nS)
VGAT-I (12)	Expiration	0.007 ± 0.001	0.087 ± 0.012
	Inspiration	0.186 ± 0.036	0.167 ± 0.044
VgluT2-I (18)	Expiration	0.007 ± 0.001	0.236 ± 0.045
	Inspiration	0.168 ± 0.020	0.117 ± 0.026
VGAT-E (17)	Expiration	0.006 ± 0.001	0.073 ± 0.009
	Inspiration	0.035 ± 0.007	0.408 ± 0.058
VgluT2-E (1)	Expiration	0.007 ± 0.000	0.073 ± 0.000
	Inspiration	0.094 ± 0.000	0.270 ± 0.000

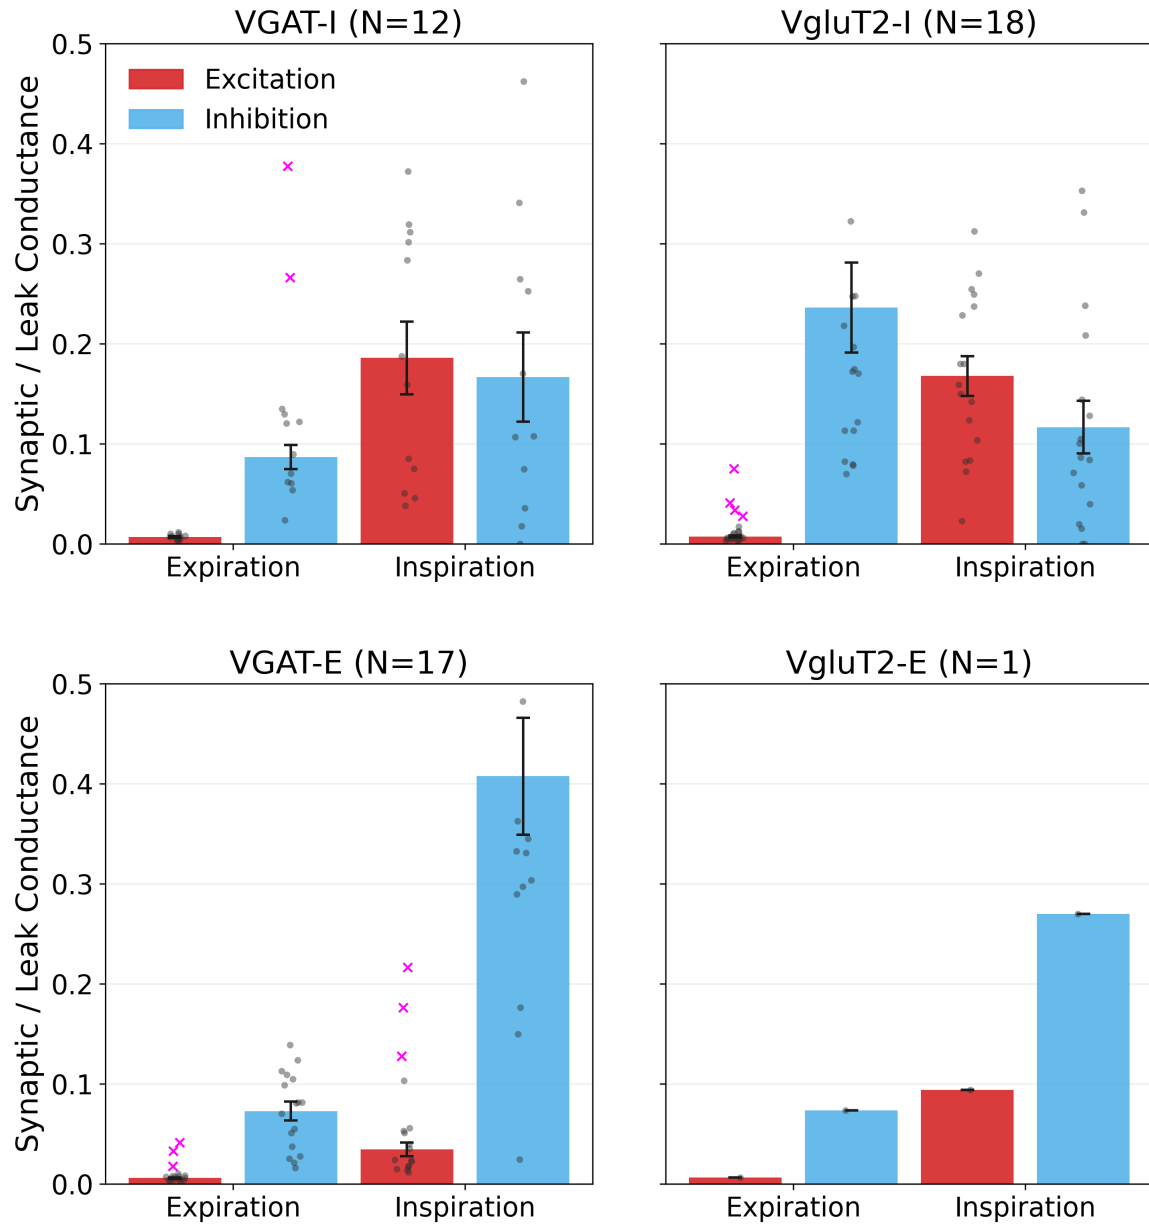

Figure 3: Population-level summary of excitatory and inhibitory conductances during expiration and inspiration for the four main groups (VGAT-I, VgluT2-I, VGAT-E, VgluT2-E). Bars represent mean $\pm$ SEM of inliers. Outliers were detected and removed via the IQR method. Individual cells are overlaid as dots (inliers) and 'x' markers (outliers). Synaptic conductances are expressed in nS.

3.3 Inferred Circuit Connectivity

Based on these observations, we can infer the specific connectivity between these four populations (Figure 4).

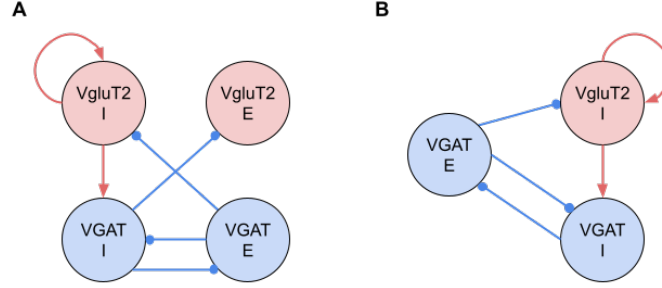

Figure 4: Proposed circuit diagram of preBötC connectivity inferred from synaptic conductance analysis. Red nodes/lines indicate (excitatory) components; Blue nodes/lines indicate (inhibitory) components. Arrows denote excitation; circles denote inhibition. **(A)** Complete connectivity graph comprising all four distinct populations defined by neurotransmitter type and firing phase. The **VgluT2-I** population provides recurrent and feed-forward excitatory drive (red arrows). Reciprocal inhibition (blue lines) enforces phase transitions: **VGAT-I** inhibits the Expiratory populations (**VgluT2-E**, **VGAT-E**) during inspiration, while **VGAT-E** inhibits the Inspiratory populations (**VgluT2-I**, **VGAT-I**) during expiration. Note that **VgluT2-E** receives phasic inhibition but does not provide significant synaptic output to other populations in this slice preparation. **(B)** The core rhythm-generating circuit. Excluding the non-driving **VgluT2-E** population highlights the essential “kernel” of the network: a self-exciting inspiratory source (**VgluT2-I**) coupled with a half-center oscillator formed by the mutually inhibitory **VGAT-I** and **VGAT-E** populations.

First, since all Inspiratory neurons (both **VgluT2-I** and **VGAT-I**) receive tonic inhibition during the expiratory phase, this inhibition must originate from the inhibitory population active during that phase: the **VGAT-E** neurons. Thus, we infer a connection from **VGAT-E** to both **VgluT2-I** and **VGAT-I**. Second, Expiratory neurons (**VgluT2-E** and **VGAT-E**) receive strong inhibition during the inspiratory phase. This inhibition must similarly arise from the inhibitory population active during inspiration: the **VGAT-I** neurons. This indicates a connection from **VGAT-I** to both **VgluT2-E** and **VGAT-E**. Third, the phasic excitation received by all Inspiratory neurons during their active phase must be driven by the excitatory population active at that time: the **VgluT2-I** neurons. This implies that **VgluT2-I** neurons provide recurrent excitation to themselves and feed-forward excitation to the **VGAT-I** population. Finally, the lack of significant synaptic drive received by Expiratory neurons during their active phase specifically excludes strong recurrent excitation within the **VgluT2-E** population or from **VgluT2-E** to **VGAT-E** in this slice preparation.

4 Discussion

4.1 The Core Rhythm-Generating Kernel in Reduced Preparations

The circuit topology we inferred for the rhythmic slice preparation (Figure 4B) represents a “reduced” version of the comprehensive respiratory network architecture previously described in computational reviews and modeling studies of the intact system (Smith et al., 2013; Ausborn et al., 2018). By isolating the essential components remaining in the slice, our conductance analysis bridges the gap between the complex, multi-compartmental models of the intact brainstem and the minimal logic required for rhythm generation.

4.2 Mapping the Slice Topology to the Intact Inhibitory Ring

Previous large-scale computational models have posited that the respiratory rhythm relies on a “mutually inhibitory ring” structure involving interactions between the Pre-BötC and BötC compartments. Specifically, these models suggest that the phase transitions are orchestrated by reciprocal inhibition between inspiratory (Early-I) and expiratory (Post-I/Aug-E) inhibitory populations.

Our results in the slice (Figure 4B) provide direct functional verification of this theoretical motif. The interaction we observed between **VGAT-I** (Inspiratory) and **VGAT-E** (Expiratory) neurons perfectly maps onto the core “half-center” oscillator proposed in the literature:

- **VGAT-I** corresponds to the **Early-I** population, which is driven by excitatory inspiratory neurons and provides inhibition during the inspiratory phase.
- **VGAT-E** corresponds to the lumped activity of **Post-I** and **Aug-E** populations, which enforce the expiratory pause through inhibition of inspiratory elements.

The persistence of this reciprocal inhibitory loop in the slice confirms that the “inhibitory ring” is not merely an emergent property of the intact system but is hard-wired into the local microcircuitry of the Pre-BötC and BötC, serving as the fundamental timing mechanism even in reduced preparations (Marchenko et al., 2016). As recently elaborated by Molkov et al. (2025), this local circuit likely represents a scalable logic: in the intact brainstem, the single “lumped” VGAT-E population identified here differentiates into distinct Post-I and Aug-E populations to allow for finer control of expiratory duration and phase transitions.

4.3 Synaptic Coordination and Global Architecture

Our results highlight the primacy of synaptic architecture in coordinating population activity. Rather than serving merely as a trigger for rhythm generation, the strong recurrent excitation within the VgluT2-I population acts as a synchronization mechanism, ensuring coherent network-wide output once the burst is initiated. Indeed, the high excitation-to-inhibition ratio we inferred for these neurons constitutes a “synaptic fingerprint” that allows for the identification of this critical Dbx1-derived “rich-club” across preparations (Molkov et al., 2025).

Crucially, the interaction between VGAT-I and VGAT-E forms a “synaptic scaffold” that enforces phase-locking and defines the inter-burst interval. This local inhibitory circuit represents a modular building block for the global “inhibitory ring” described in intact systems, where the “lumped” VGAT-E population expands to coordinate diverse behaviors (Molkov et al., 2025). Within this functional connectome, the VgluT2-E population exists as a “latent” node—functionally passive in the slice but structurally hard-wired to participate when recruited by metabolic demand, consistent with the Triple Oscillator Hypothesis (Anderson and Ramirez, 2017). Finally, this robust inhibitory scaffold provides a stable temporal lattice that may serve as a global clock for synchronizing higher-order non-respiratory functions, from whisking to memory consolidation (Molkov et al., 2025).

5 Conclusion

The inferred circuit (Figure 4B) effectively strips away the “conditional” layers of the respiratory network—such as the active expiratory oscillator and long-loop pontine feedback—to reveal the minimal rhythmogenic structure. This structure consists of a self-exciting inspiratory pacemaker (**VgluT2-I**, analogous to Pre-I/I) constrained by a robust, reciprocal inhibitory scaffold (**VGAT-I** $\leftrightarrow$ **VGAT-E**). This confirms that the theoretical “core microcircuit” proposed in previous modeling studies (Molkov et al., 2017) is physically instantiated in the local synaptic architecture of the ventrolateral medulla, providing the necessary timing mechanism for rhythmic coordination.

Supplementary Note: Dynamic Estimation of Inhibitory Reversal Potential (E_i)

The synaptic conductance reconstruction method relies on the precise knowledge of the inhibitory reversal potential (E_i). While theoretical values (e.g., -80 mV) are often used, the effective E_i can vary significantly across preparations. To ensure assumption-free reconstructions, we implemented a data-driven geometric algorithm to estimate E_i directly from the experimental data.

Geometric Rationale

The relationship between total conductance ($G_{tot}(\phi)$) and the current y-intercept ($I_0(\phi)$) defines a “wedge” in the G_{tot} - I_0 plane. In the absence of excitatory drive ($g_e(\phi) = 0$), the current balance

equation dictates a linear relationship whose slope is determined by E_i :

$$I_0(\phi) = -E_i G_{tot}(\phi) + I_{Li} \quad (11)$$

where $I_{Li} = g_L(E_i - E_L)$ is the leak current at the inhibitory reversal potential as defined in the Methods. Geometrically, the line of pure inhibition defined by Equation 11 forms a strict upper boundary for the data trajectory in the wedge plot.

Tight-Fit Geometric Algorithm

To estimate E_i robustly, we use a geometric pivoting algorithm that identifies the optimal value of E_i such that Equation 11 acts as a global upper bound for all observed regression points $(G_{tot}(\phi), I_0(\phi))$. The algorithm selects E_i to minimize the area between this boundary and the data points while observing the global bounding constraint. This approach provides a physically motivated, preparation-specific estimate of E_i , ensuring that the subsequent decomposition into excitatory and inhibitory conductances is consistent with the global statistical limits of the recording.
